FIGURE I: PREPROCESSING PIPELINE

Abstract— Localization is a fundamental capability for autonomous robots, enabling them to operate effectively in dynamic environments. In Robocon 2025, accurate and reliable localization is crucial for improving shooting precision, avoiding collisions with other robots, and navigating the competition field efficiently. In this paper, we propose a hybrid localization algorithm that integrates classical techniques with learning-based methods, relying solely on visual data from the court's floor to achieve self-localization on the basketball field.

Keywords—Robot Localization, Autonomous Navigation, Neural Networks, Robocon

I. Introduction

Section II reviews existing methods and prior research related to this work. Section III provides a detailed description of our proposed algorithm, approach, and model architecture. Section IV provides the results obtained from our experiments. Section V evaluates the accuracy of our approach and discusses potential directions for future work.

II. RELATED WORK

III. METHODOLOGY

Our approach is a two-step process that begins with **Preprocessing** the image, followed by passing it to the model for **Inference**.

A. Preprocessing

The input image having dimensions ($640 \times 480 \times 3$) is converted from the RGB color space to the HSV color space, then the white regions are masked out using two predefined HSV ranges. The image is downsampled through a radial scan, flattened, and finally passed through the neural network.

Algorithm 1 Downsampling

```
Input: Image
 1: H \leftarrow \text{Image.height}
 2: W \leftarrow \text{Image.width}
 3: R \leftarrow \text{Black Image}
 4: for angle \leftarrow 0 to 180 step 2 do
        lastPixel \leftarrow 0
        cx \leftarrow W / 2
 6:
        cy \leftarrow H
 7:
 8:
         for d \leftarrow 0 to max(H, W) do
             x \leftarrow cx + d \times \cos(angle)
 9:
              y \leftarrow cy - d \times \sin(angle)
10:
              if 0 \le x < W and 0 \le y < H then
11:
                  pixel \leftarrow Image[y][x]
12:
                  if lastPixel = 255 and pixel \neq 255 then
13:
                       R[y][x] \leftarrow 255
14:
                  end if
15:
                  lastPixel \leftarrow pixel
              end if
17:
         end for
18.
19: end for
20: Return R
```

B. Model Architecture

The proposed model is a feedforward neural network consisting of a flattening layer followed by four fully connected layers. The first 200 pixels from the top of the image are removed to reduce the input size, as they do not carry useful information.

The resulting image with dimensions $(640 \times 280 \times 1)$ is flattened into a vector of size 1,79,200 and passed through the first linear layer, followed by a ReLU activation function. The subsequent layers have sizes 1024, 256, and 64, each followed by a ReLU activation. The final layer outputs a 2-dimensional vector representing the predicted x and y positions of the robot.

The rationale for using this relatively simple model lies in the simplicity of the input images and to reducing inference time.

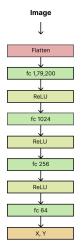

FIGURE II: ARCHITECTURE DIAGRAM

C. Dataset

A digital twin of the robot was created and simulated in a replica of the Robocon 2025 arena using the Gazebo [1] simulator with the help of ROS 2 [2].

The robot was driven through the arena capturing images and corresponding x, y coordinates. A TimeSynchronizer was used to synchronize the frame header and the position header. A total of 6283 images were captured and split into training and

test datasets with a 0.9 to 0.1 ratio. Care was taken to include every part of the arena for an unbiased dataset.

D. Training

The model was trained for 15 epochs using an Adam optimizer [3] with an initial learning rate of 10^{-4} and a Mean Squared Error (MSE) loss function.

IV. RESULTS AND ANALYSIS

V. Conclusion
